S1 XAS Characterizations

The X-ray absorption spectroscopy (XAS) measurements were performed at the Canadian Light Source (CLS) located at the University of Saskatchewan, a 2.9 GeV third-generation synchrotron source. The Fe and Co K-edge X-ray absorption near-edge structure (XANES) and Extended X-ray Absorption Fine Structure (EXAFS) were collected on the 06ID-1 Hard X-ray MicroAnalysis (HXMA) beamline. The experiment was performed in fluorescence mode using a Canberra 32 Ge germanium array detector.[1] In the experiment, a Si(111) monochromator crystal and Rh mirrors (collimating and focusing mirrors) were used during data collection. The beamline monochromator was detuned to 50% of its full flux to reduce the impact of the X-ray beam's high harmonic components; the detune energy point was set at the end of the XAFS data collection energy range at 13.0 Å⁻¹. The monochromator energy was first calibrated at the Co K-edge using Fe and Co reference foils from the EXAFS Materials Inc.. The same reference foil was arranged between the ionization chamber detector I1 and I2 throughout the Co experiment. Therefore, the in-step energy calibration is available for each scan. 100% helium gas was used in all three ionization chamber detectors during the experiment. The scan step-sizes used were 10 eV/step, 0.2 eV/step, and 0.05 Å⁻¹/step, respectively, for the pre-edge from -200 to 30 eV, XANES from -30 to 40 eV, and XAFS regions from 40 eV to 12 Å⁻¹ of the data range.[2]

Analyses of both the near edge (on an energy scale) and extended range (in the R space) XAS spectra were performed using Athena software.

S2 Liquid Zinc-air Battery Assembly

The zinc-air batteries were tested in home-built electrochemical cells; the electrolyte was 1.0 or 6.0 M KOH with a 0.2 M zinc acetate solution. The Liquid rechargeable zinc-air battery was assembled with current collectors (nickel foam for cathode), a polished zinc plate, and a catalyst layer (CL) coated gas diffusion electrode (GDE). To prepare the air electrode, a definite volume of homogeneous catalyst ink consisting of Fe/Co-CTs/CNTs catalyst, Nafion solution (5 wt.%), and isopropanol was dropped onto a gas diffusion layer (GDL) (loading: 2 mg cm^{-2}) with an exposed active area of 1.13 cm^2. Then Ni foam, GDE, and hydrophobic and breathable membrane were pressed together to form the integrated air electrode. For comparison, batteries using Fe/Co-CTs/NC and 20 wt.% Pt/C catalysts were fabricated by the same method. Polarization data were collected using a galvanodynamic method at a scan rate of 1.0 mA s^{-1}.

S3 Fuel Cell Test

Catalyst ink was prepared using the following procedure: 10 mg of the catalyst was mixed with 272 mL of a 5% Nafion solution, 206 mL of ethanol, and 147 mL of deionized (DI) water. The mixture underwent sonication for 15 minutes, followed by agitation for another 15 minutes. Then, 284 µL of this ink was dispensed onto a 1.14 cm² carbon paper (Sigracet 25BC from Ion Power) and dried at 80°C for 1 hour to form the Gas Diffusion Electrode (GDE) for the cathode. The ratio of Nafion to the catalyst was maintained at 1.25. The Membrane Electrode Assembly (MEA) was fabricated by sandwiching a 211 membrane between the cathode GDE and a commercially sourced Pt/C anode GDE. During testing, the flow rates of H$_2$ and O$_2$ were both maintained at 0.3 Normal Liters Per Minute (NLPM) with a backpressure of 0.5 bar, and the cell temperature was held at 80 °C.

S4 Calculation

Tafel plot calculation and electron transfer number calculation were based on the previously reported method.[1, 3] ECSA was calculated using ECSA= $C_{dl}/(40*m_{loading})$, where m$_{loading}$ is the loading mass of the catalyst per geometrical area of the electrode. The C_{dl} (double-layer capacitance) was determined by measuring the capacitive current associated with double-layer charging from the scan-rate dependence of cyclic voltammetric stripping. For this, the potential window of cyclic voltammetric stripping was about 1.1 V to 1.19 V versus RHE (1.0 M KOH solution). The scan rates were 5 mV s^{-1}, 10 mV s^{-1}, 15 mV s^{-1}, 20 mV s^{-1} and 25 mV s^{-1}. The C_{dl} was estimated by plotting the j$_a$ at 0.59 V (where j$_a$ are the c anodic current densities) versus RHE against the scan rate, in which the slope was the C_{dl}.

S5 Computational Methods

All the first-principles DFT calculations in this work were performed without symmetry restrictions using the Vienna ab initio simulation package (VASP) code. For these calculations, we used the parametrization of Perdew-Burke-Ernzerhof of the exchange-correlation functional within the generalized gradient approximation (GGA) formalism. No dispersion correction has been included in the calculation as it should be negligible in such compact systems involving covalent bonds. The energy cut-off was set to 400 eV while the Brillouin zone was sampled on 4×4×4 Gamma-Pack k-point grid. An initial graphene sheet, represented by a periodic plate with cell dimensions of a = 12.74 Å and b = 15.00 Å, was used to model the carbon support. A 20 Å thick void layer was included in the z-direction

to minimize possible artificial interactions between the periodic sheets. A number of carbon atoms were removed from the slab and replaced by FeN_x and/or CoN_x moieties. All atomic positions in the supercell were fully relaxed without any constraints using the conjugate gradient algorithm, and the total energy convergence criterion was set to 10^{-6} eV. We have optimized four structures, as illustrated in Fig. S1.

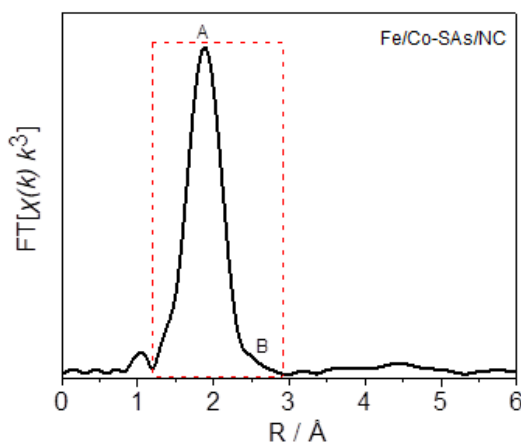

Fig. S17 Fe XAFS data from Fe/Co-SAs/NC: EXAFS in the magnitude of Fourier transform for $k^3\chi(k)$ with nearest neighbor features "A" and "B" indicated

EXAFS characterization was guided by the theoretical DFT modeling and focused on the nearest neighbor Fe local structural environment. The latter is attributed by EXAFS to the experimentally resolved first shell Fourier transform (FT) peak with its major feature peaked as "A" at around 1.41 Å and a shoulder feature "B", carried on the high R wing side of the feature "A". Guided by the DFT models FeCo-N_6, Fe-N_2C_2, Fe-$N_{2\times2}$, and Fe-N_4 (see Fig. S1), the corresponding Fe local structural environment was derived and used for theoretical amplitudes and phases scattering calculation by using the software Feff 7.02 (Rehr and Albers, 2000), respectively, guiding the followed EXAFS R space curve fitting.

The XAFS data reduction and the followed R space curve fitting were performed using ATHENA software (Ravel and Newville, 2005) and WINXAS (version 2.3, Ressler, 1997), respectively. The first inflection point of the Fe K edge XANES was defined as the experimental E_0, and the post-absorption edge background was estimated by the cubic spline fit. The Gaussian window function was used for Fourier transform over k data range of 2.5-10.7 Å^{-1} for $k^3\chi(k)$ with a window parameter of 30%. The R space curve fitting was performed for R data window 0.8-2.4Å.

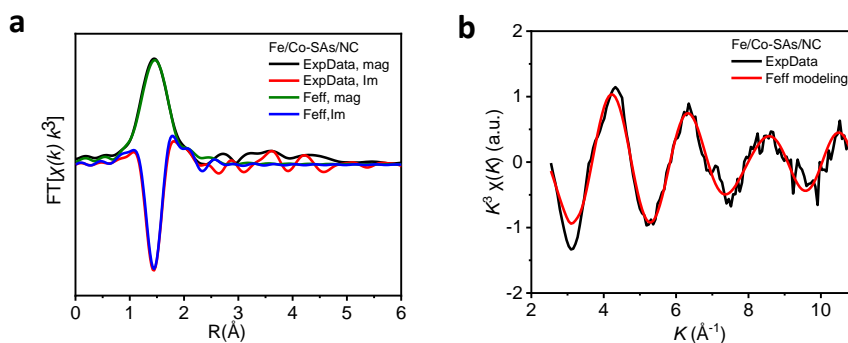

Fig. S37 Comparison is made for a) the magnitude and the imaginary part of Fourier transform between the experimental and the Feff modeling; and b) $k^3\chi(k)$ between the experimental and the Feff modeling based on the R space curve fitting result for the Fe/Co-SAs/NC after OER

The fitted parameters from the corresponding fitting are summarized in Table S3. OER enhanced the stability of the local structural environment FeN$_4$ configure, illustrated by significantly decreasing the DW parameters by 68% and 31% for paths Fe-N and Fe-C, respectively. But OER has no impact on the geometry of the FeN$_4$ configure and its nearest neighbor C coordination. c-d) Geometric structure of the FeN$_4$ sites before and after OER process.

Fig. S38 Comparison is made for the magnitude and the imaginary part of Fourier transform between the experimental and the Feff modeling for the Fe/Co-SAs/NC after OER. The fitted parameters from the corresponding fitting are summarized in Table S4
